Pain and functional changes after lumbar spine surgery: a prospective cohort study with three years follow-up. Lumbar spine surgery is a widely used treatment for low back pain, but it is uncertain which patients will benefit and which will experience persistent symptoms and disability. The objective of this study was to prospectively investigate the variables associated with adverse functional status and pain after lumbar spine surgery. A prospective cohort study with a maximum follow-up of three years. Two hundred and forty-seven patients undergoing lumbar spine surgery for degenerative or spinal malignancy. Outcomes measured at baseline and at follow-up using the pain subscale of the Back Disability Questionnaire, the Roland Morris Disability Questionnaire, the Visual Analog Pain Scale and the Short Form-36. Fifty-one percent of patients had a severe disability or handicap at baseline, and the mean duration of the symptoms was 32 months. At follow-up, 69% had an improved functional status and there was a strong correlation between the pain and disability scores. Male gender was associated with a better outcome. Ankylosing spondylitis and the number of levels operated were associated with a worse outcome. Surgery for isolated radiculopathy improved the pain score significantly. Patients who had a shorter time period to hospital discharge had a better outcome. The mean duration of surgery was 146 minutes. An increase in the number of procedures carried out during the study was associated with an improvement in the pain score. Operative treatment for low back pain is associated with favourable functional status if the patient has acceptable pain. Male gender, shorter duration of hospital stay and isolated radiculopathy are associated with better postoperative outcomes. Surgery for isolated radiculopathy also improved pain scores. As surgery was associated with improvements in disability and pain, it may be that it is the opposite outcome of the results of conservative treatments.
